Current diagnosis and treatment of basal cell carcinoma.

ABSTRACT
Basal cell carcinoma represents the most common tumor in fair-skinned individuals. In Germany, age-standardized incidence rates are 63 (women) and 80 (men) per 100,000 population per year. Early lesions may be difficult to diagnose merely on clinical grounds. Here, noninvasive diagnostic tools such as optical coherence tomography and confocal laser scanning microscopy may be helpful. The clinical diagnosis is usually confirmed by histology. Standard therapy consists of complete excision with thorough histological examination, either by means of micrographic surgery or, depending on tumor size and location as well as infiltration, using surgical margins of 3-5 mm or more. In particular, multiple basal cell carcinomas (such as in Gorlin-Goltz syndrome) and locally advanced as well as rarely also metastatic basal cell carcinoma may pose a therapeutic challenge. In superficial basal cell carcinoma, nonsurgical therapies such as photodynamic therapy or topical agents may be considered. In case of locally advanced or metastatic basal cell carcinoma, an interdisciplinary tumor board should issue therapeutic recommendations. These include radiation therapy as well as systemic therapy with a hedgehog inhibitor. © 2015 Deutsche Dermatologische Gesellschaft (DDG). Published by John Wiley & Sons Ltd. PMID: 26882375
